Histology and Histopathology

Ultrastructure of the chronically vagotomised atrial myocardium in the monkey *(Macaca fascicularis)*

W.C. Wong, T.Y. Yick and E.A. Ling
Department of Anatomy, National University of Singapore, Kent Ridge, Singapore 0511

Summary. The ultrastructure of the atrial myocardium in the monkey *(Macaca fascicularis)* was studied after bilateral cervical vagotomy and survival times of 100, 175 and 367 days. Changes were observed in the nucleus and the cytoplasm of the myocyte. Sequestered within the nuclei of the affected myocytes were cytoplasmic organelles and inclusions. In the late stages, there was a tendency towards condensation and margination of the heterochromatin. Changes in the cytoplasm included increased glycogen, mitochondrial degeneration and myofibrillar disorganisation and degeneration. There was increased collagen and mononuclear cell infiltration in the extracellular space in the later stages. This study has shown that the long term structural integrity of the atrial myocyte depends on an intact vagal innervation. The survival of the monkey after chronic bilateral vagotomy suggests that this nonhuman primate is a suitable model for functional studies of the parasympathetically denervated heart.

Key words: Ultrastructure, Vagotomised, Myocardium, Monkey

Introduction

Although the normal ultrastructure of the mammalian atrial myocardium has been well described (Canale et al., 1986; Sommer and Jennings, 1986) accounts of the effects of vagotomy on its structural integrity are relatively few. Tchervova (1960) has described, histologically, leucocytic infiltration, dedifferentiation of connective tissue cells and myocardial fibers following vagotomy, while Chernukh et al. (1974) mentioned mitochondrial changes in their ultrastructural study. Imataka et al. (1982) observed cellular enlargement, nuclear degeneration and fibrosis in the interstitial spaces in the rabbit ventricle 7 to 8 days after a unilateral vagotomy. More recently, Wong et al. (1987) followed the sequential ultrastructural changes in the monkey's atrial myocardium up to 4 weeks after a bilateral vagotomy. In that study, it was uncertain if the observed atrophic changes were transient and reversible or prolonged and irreversible. The present study was therefore undertaken to answer that question and to describe the ultrastructural changes in the chronically vagotomised atrial myocardium in the monkey. A brief account of the results has been published (Wong et al., 1988).

Materials and methods

Six healthy adult monkeys *(Macaca fascicularis)* of either sex and weighing 2.0-4.2 kg were used. Their ages could not be ascertained as they were trapped in the wild by animal suppliers. In 3 animals, under intraperitoneal Sagatal (sodium pentobarbital 30 mg/kg) anesthesia and aseptic conditions, a ventral midline incision was made in the neck to expose both vagi. The nerves were sectioned above the omohyoid muscle and to avoid reinnervation a 10 mm length of each nerve was removed. Survival times were 100, 175 and 367 days. One monkey was sham operated in which the vagi were exposed but not sectioned and was allowed to survive 175 days. The 2 remaining monkeys were used as unoperated controls. At the time of sacrifice each animal was reanesthetized and received artificial respiration through a tracheostomy by a Palmer animal ventilator. The mediastinum was exposed and the pericardium slit to allow the routine intraventricular injection of 1000 units of heparin (1 ml) and 1 ml of 1% sodium nitrite per kg body weight. The animal was rapidly perfused through the left cardiac ventricle with 500 ml of Ringer's solution at pH 7.3-7.4 followed by 1000 ml of dilute fixative (1% paraformaldehyde + 1.25% glutaraldehyde) and then 2000 ml of concentrated fixative (4% paraformaldehyde + 5% glutaraldehyde) in 0.1M cacodylate buffer at pH 7.4.

After perfusion, the heart was removed and placed in

fresh concentrated fixative overnight at 4°C. The interatrial septum was carefully dissected out and trimmed into approximately 1 mm cubes which were placed in ice-cold 0.1M cacodylate buffer (pH 7.4) containing 5% sucrose. Following 2 changes of buffer at intervals of 10 minutes, the tissues were post-fixed in ice-cold 1% osmium tetroxide containing 1.5% potassium ferrocyanide (Hayat, 1981) for 2 hours. The tissue blocks were then dehydrated in an ascending series of ethanol and embedded in Araldite.

Semithin 1μm thick sections were cut with Porter-Blum MT, or Reichert OMU4 ultramicrotomes and stained with 1% methylene blue and azure II. Selected areas of the blocks containing the atrial myocardium sectioned longitudinally or transversely were trimmed for ultrathin sectioning. The ultrathin sections were mounted on coated grids, doubly stained with uranyl acetate and lead citrate and viewed in a Philips 400T or Jeol 1200 EX electron microscope.

Results

Control animals

The ultrastructure of the atrial cells in the sham operated and unoperated controls (Figs. 1, 2) resembled that described previously in the monkey (Wong et al., 1987) and in other mammals. The nucleus was usually central but may occasionally be subsarcolemmal in position. The nuclear outline, though relatively smooth in most cells may be indented in some. The nucleoplasm contained evenly dispersed chromatin with small amounts of heterochromatin on the inner aspect of the nuclear envelope. Mitochondria were abundant but giant forms were rarely encountered. Glycogen was present as beta particles in the sarcoplasm and occasionally within mitochondria. Atrial granules, sarcoplasmic reticulum and typical intercalated discs were readily identified.

Experimental animals

A spectrum of abnormal myocytic profiles was seen in the chronically vagotomised myocardium. Changes were observed in the nucleus and cytoplasm.

Cytoplasmic organelles and inclusions such as mitochondria, atrial granules, sarcoplasmic reticulum, tubulovesicular structures, myofilaments, lipid droplets and electron-dense bodies were located within deep nuclear invaginations which communicated with the cytosol (Figs. 3, 4). In other instances, the cytoplasmic organelles were apparently lying freely in the nucleoplasm (Figs. 4, 5). The outlines of other nuclei were deeply indented assuming polylobular forms (Fig. 6). The chromatin in these and other nuclei was patchily distributed. There was a tendency towards condensation and margination of the heterochromatin, especially in the later stages.

The sarcolemma of some atrial cells was deeply folded with outpockets or cell projections resulting in peripheral displacement of the nucleus (Fig. 7). Giant mitochondria (Figs. 7, 8) were more commonly seen than in control animals. Many mitochondria showed disintegration of cristae, vacuolation and sequestered glycogen granules (Figs. 4, 8, 9). Glycogen granules were increased in many myocytes with the formation of alpha particles, hardly encountered in control animals (Fig. 10). Large glycogen deposits may entrap within themselves mitochondria which undergo dissolution (Fig. 11).

Myofibrillar disorganisation was reflected in a general edema of the myocyte, loss of myofilaments and distortion, fragmentation or disappearance of Z discs (Figs. 12, 13). The loss of myofilaments in the myocytes may be replaced by a proliferation of sarcoplasmic reticulum, mitochondria and accumulation of alpha glycogen particles (Fig. 10) or an undefined granular substance in the cytosol (Fig. 12).

There was increased collagen in the extracellular space, especially in the 175- and 367-day animals with infiltration of mononuclear cells (Fig. 14), some of which were in close relation with myocytes (Fig. 15).

Discussion

The present study provides the first direct evidence that the long term structural integrity of the atrial myocardial cell is dependent upon an intact vagal innervation. As an extension of our earlier observations (Wong et al., 1987), the present results also suggest that the ultrastructural changes in the chronically vagotomised myocardium are progressive and irreversible. These changes may be attributed to the bilateral vagotomy as none were observed in the sham operated or unoperated control animals. Moreover, experimental and control animals were subjected to a similar procedure before and during perfusion.

The intranuclear inclusion of cytoplasmic organelles and inclusions observed in the present study compare with those described in a variety of normal, degenerating and diseased mammalian tissues (Leduc and Wilson, 1959; Brandes et al., 1965; Bloom, 1967; Sobel et al., 1969; De Lellis et al., 1980; Sanford et al., 1987), including human myocardial cells in coronary heart disease (Schaper and Schaper, 1986). Interestingly, the nuclei of smooth muscles in the cerebral artery wall also assumed polylobular forms after long-term sympathectomy (Dimitriadou et al., 1988).

Various explanations have been proposed to account for the phenomenon. They include undulation of the nuclear envelope and lobulation of the nucleus (Brandes et al., 1965; De Lellis et al., 1980), abnormal or unusual mechanisms during cell growth (Brandes et al., 1965; Bloom, 1967) and the maintenance of a constant ratio of nuclear surface to nuclear volume (Leduc and Wilson, 1959; Sanford et al., 1987). In the present study, the second alternative is not likely since such nuclear profiles were not encountered in the control animals; nor indeed were they in the short-term survival studies (Wong et al., 1987). The invagination of the nuclear membrane resulting in an increase of the nuclear surface may reflect functional demands, since in the atrophic myocytes there was degradation and degeneration of cytoplasmic organelles.

A lowered pH has been associated with ultrastructural changes in the myocardium, including aggregation of nuclear chromatin (Armiger et al., 1977). In the present results the changes observed in the nuclear chromatin could be a reflection of the accumulation of metabolites or breakdown products in the atrophied myocytes. Such changes may be indicative of cell injury.

In the experimentally-induced ischemic myocyte there is a rapid depletion of glycogen due to the acceleration of glycogenolysis and anaerobic glycolysis (see Reimer and Jennings, 1986). In contrast, in the chronically vagotomised myocyte there is increased glycogen, possibly due to decreased demand or accelerated synthesis. The deformation and disintegration of the mitochondria entrapped within the large glycogen deposits could be a mixed physical and chemical phenomenon. Another feature is the increased glycogen within the mitochondria. Intramitochondrial glycogen has been reported in normal rat retinal receptors (Ishikawa and Pei, 1965), frog spinal ganglia (Berthold, 1966) and dystrophic axons (Lampert, 1967) among others. An occasional glycogen granule has been observed by us in the normal myocyte. The abnormal accumulation may be due to a decreased demand and metabolism.

Tomanek and Cooper (1981) have demonstrated the role of stretch and/or tension in maintaining the structural integrity of the myocardial cell by severing the chordae tendineae of a ventricular papillary muscle. They described rapid and marked cellular degeneration in the myocytes. In the present study, the bilateral section of the vagus nerves would have interrupted not only their efferent but also their afferent components which are concerned with the cardiac reflexes (Higgins et al., 1973; Corr et al., 1986). Sectioning of the vagus nerves would remove the parasympathetic innervation to the atrium and abolish these reflexes. This could be a contributing factor to the changes in the myocytes which

included myofibrillar degeneration and extensive loss of contractile elements.

While bilateral vagotomy in the present study has been shown to be correlated with degenerative changes in the atrial myocardium, whether the operation also affected its functional integrity and to what degree is not known. Previous functional studies have emphassied the poor survival of animals after a bilateral cervical vagotomy (Sharpey-Schafer, 1920; MacCanon and Horvath, 1957; Schmitt and Meyers, 1957; Sloan et al., 1959; Shephard and Whitty, 1964). Consequently, it has been difficult to obtain a chronically parasympathectomised heart (Kaye, 1984). Some observations on the isolated cat papillary heart muscle one week after a bilateral cervical vagotomy (Vergara and Penna, 1984) suggest a possible modulatory role of the vagus nerve in the synthesis and/or release of the adrenergic neurotransmitter in the ventricular myocardium. The present successful survival of our animals following chronic bilateral cervical vagotomy, coupled with our earlier shorter term study (Wong et al., 1987) suggests that the monkey could serve as a suitable experimental model for functional studies of an extended timeframe of the parasympathetically denervated heart.
